(Received 19 February 2008; published 21 May 2008)

Sodium ion ordering on an \textit{in situ} cleaved Na$_2$CoO$_2$ ($x = 0.84$) surface has been studied by ultrahigh vacuum scanning tunneling microscopy at room temperature. Three main phases, with $p(3 \times 3)$, $(\sqrt{7} \times \sqrt{7})$, and $(2\sqrt{3} \times 2\sqrt{3})$ hexagonal unit cells and a surface Na concentration of $1/3, 3/7, 1/2$, respectively, were identified. One surprising finding is that Na trimers act as the basic building blocks that order in long range. The stability of Na trimers is attributed to the increased Na coordination with oxygen as indicated by \textit{ab initio} calculations, and possibly at finite temperature by configuration entropy.

The conducting layered sodium cobaltate, Na$_2$CoO$_2$, exhibits a series of surprising electronic or magnetic properties with Na concentration $x$ [1]. Hydrated Na$_{0.3}$CoO$_2$.1.3H$_2$O is superconducting [2]. At $x = 0.5$, an unexpected insulating state below $\sim 51$ K is observed [3,4]. For $x \approx 0.55$, the material has a “Curie-Weiss metal” behavior, and A-type antiferromagnetic ordering below $\sim 22$ K is found for $x \approx 0.75$ [1,5,6]. Na$_2$CoO$_2$ also shows large thermopower enhancement at high $x$ [7]. Despite these intense research efforts, exact Na ordering and its subtle role remains largely uncertain, although its importance has been acknowledged [8]. If stable Na ordered patterns exist [4,9,10], the electronic or magnetic properties of the Co$_2$ layers could be affected by, e.g., reconstructed Fermi surface [11,12], Coulomb potential landscape [13,14], or coexistence of localized spins and itinerant charges [15]. It is thus important to understand the principle of Na ordering. Here, we report the first scanning tunneling microscopy (STM) study of Na ordering on a Na$_2$CoO$_2$ surface. Our study has one unique advantage, i.e., structure models based on real-space Na arrangement can now be analyzed, shedding new light on the mutual Na$^+$-Na$^+$ and Na$^+$-Co$^{3+/4+}$O$_2$ interactions. We found a new guiding rule for Na ordering, viz, Na atoms form trimers that act as the basic building blocks for surface Na ordering.

Generally, the driving force of Na ion ordering is thought to be electrostatics [9,14], which maximizes Na-Na separation. Although many experimental and theoretical studies are thus interpreted, inconsistency is common. Various Na ordered structures observed by electron, x-ray, and neutron diffraction [4,13,14,16] are often at odds with theoretical predictions [9,10,13,14,17]. This is perhaps due to sample quality variation, Na concentration uncertainty, probe beam induced damage, and computation limitation. The Coulomb repulsion between Na cations can also lead to unintuitive structure. A recent study [14] reveals the formation of ordered vacancies at some simple fractional fillings for $x > 0.5$. Inside each vacancy, there exists a Na monomer or a Na trimer occupying Na(1) sites that sit atop Co atoms. We found that this multivacancy model and Na trimer geometry explain the observed superstructures of $x = 0.84$ and $x = 0.71$ crystals very well [15]. In Ref. [14], the proposed vacancy models apply to $x \approx 0.5$. For $x < 0.5$, Na cations are still presumed to repel each other [9,14,17]. In this work, we observed unexpected Na trimer ordering with surface concentration $x_s \approx 0.5$, i.e., $x_s = 1/3, 3/7, 1/2$ with STM. The simple rule of minimizing Na-Na Coulombic repulsion thus fails, indicating an unknown driving force that binds Na ions into clusters. We shall suggest that the Na trimer is stabilized by increased Na coordination with oxygen [8] and possibly at finite temperature by configuration entropy, and the trimer structure is likely relevant to bulk Na ordering.

Bilayer $\gamma$-phase Na$_{0.84}$CoO$_2$ single crystal was grown using an optical floating-zone method, and the Na content was confirmed to be ($0.84 \pm 0.02$) through electron probe microanalysis [18]. Cobaltate crystals ($\sim 2 \times 2 \times 0.5$ mm) were cleaved \textit{in situ} in UHV at room temperature and imaged with an Omicron VTSTM in a chamber described previously [19]. The cleaved surfaces showed steps that are multiples of half unit cell height ($c/2$), with $c \sim 10.8$ Å. This is consistent with the $x$ vs $c$ relation [1,20] and the weaker interactions between adjacent Co$_2$ planes. The ordered Na patterns were consistently observed in $\sim 20$ samples from two synthesized batches.

Clearly, the surface Na concentration $x_s$ is not necessarily 0.84. In the $\gamma$-phase cobaltate, Na atom sits in a trigonal prismatic cage formed with identical oxygen triangles above and below it [21]. Therefore, $x_s$ is expected to be around half of the bulk concentration, i.e., 0.42. Experimentally, we observed three Na ordered patterns, with $p(3 \times 3)$, $(\sqrt{7} \times \sqrt{7})$, and $(2\sqrt{3} \times 2\sqrt{3})$ unit cells (Fig. 1), and proposed concentrations $x_s = 1/3, 3/7, 1/2$ (Fig. 2), respectively. The concentration of 3/7 is very close to half of the bulk concentration and indeed has been most often observed than the other two phases.
The observed patterns are related to Na atoms rather than "solid" phases (not shown). These results indicate that mobile defects and coexisting mobile "liquid" and surface; (3) the hex phase can fluctuate with time, showing (2) the population of each pattern varies in each cleaved positions. Na atoms thus must have repelled each other toward the two next preferred Na(1) sites, presumably due to Coulomb interaction. Such "Na(2) → Na(1)" displacement, as denoted by the arrows in Fig. 2(a), leads to "expanded" trimers. We also note that in contrast to the suggested (√3 × √3) ordering [4,17], the real-space p(3 × 3) kagome Na ordering is unexpected and should be reexamined for its potential relevance to the superconductivity in hydrated sodium cobaltate (χ = 1/3), where water layer could serve as a buffer zone to allow surface-like kagome Na ordering.

The structure model of the hex phase (χ = 3/7) consists of ordered trimer clusters, as shown in Fig. 2(b). Our data show that each protruded dot is significantly larger in size than that in the kagome phase. Each dot can show two or three different topographic contrasts [circle in Fig. 1(b)],
FIG. 2 (color online). Proposed structure models of the (a) kagome \((x_s = 1/3)\), (b) hex \((x_s = 3/7)\), and (c) pinwheel \((x_s = 1/2)\) phases, which consist of ordered superlattices of Co-, O-, Co-centered Na(2) trimers, respectively. In the 2(b) legend, Na(1), Na(2), oxygen sites are denoted. A 3D model is shown in (d) (see also, e.g., [24,25]). All arrows denote the allowed Na(2) \(\rightarrow\) Na(1) site switching paths. In (b), the dashed circles denote concerted rotation of the Na trimers (triangles). One substrate mirror plane \((M)\), two mirror domains intersected at 21.8°, and an interstitial Na atom \((A)\) at a Na(2) site are also shown. In (c), each pinwheel segment (trimer) can also “rotate” (see dotted triangles) and renders itself triangle-like [see Fig. 1(f)]. For details of each model, see text.

suggesting that it is an Na atom cluster rather than a single Na atom. We propose that each dot is an O-centered Na trimer. Because of the ionic radius and Coulomb repulsion of Na⁺, neighboring Na(1) and Na(2) sites cannot be simultaneously occupied. An O-centered trimer thus occupies either all Na(1) or Na(2) sites. Figure 1(e) suggests that each trimer rotates concerted around its center (O site) at room temperature, smearing out resolution of individual Na atoms. We believe that the hex phase trimers are also expanded in size. We also observed dimmer interstitial Na atoms exclusively at the same half of the unit cell [e.g., letter \(A\) in Fig. 1(e)]. This corroborates with the proposed \((\sqrt{7} \times \sqrt{7})\) unit cell and the bright dot as a cluster. Mirror hex domains intersected at \(\approx 22°\) \((21.8°\) predicted) were also observed [Fig. 1(h)]. The vertical mirror planes are along \([120]\), and one such plane is denoted as \(M\) in Fig. 2(b). We note that such mirror domains exist either on the surface or in the bulk; e.g., we have observed \((\sqrt{13} \times \sqrt{13})\) mirror domains for bulk \(x = 0.84\) using x-ray Laue diffraction [15].

Figure 2(c) shows the proposed \((2/3 \times 2/3)\) pinwheel phase model \((x_s = 1/2)\). In this phase, individual Na atoms were barely resolved, suggesting dynamic switching of occupied Na sites. Each pinwheel segment appears triangle-like [Figs. 1(c) and 1(f)], cf. round dots in Figs. 1(b) and 1(e). To account for such a subtle difference, we assign Co-centered trimers to the pinwheel phase. In contrast to the kagome phase in which each Na(2) atom can be displaced along two possible Na(2) \(\rightarrow\) Na(1) paths, here the more crowded trimer arrangement favors only one Na(2) \(\rightarrow\) Na(1) path. This leads to the larger triangular shape of each Co-centered trimer, as shown by the dotted triangles in Fig. 2(c).

Na distribution on the cleaved surface is inhomogeneous. Nanoscale hex phase \((x_s = 3/7)\) coexists with either the kagome \((x_s = 1/3)\) or the pinwheel \((x_s = 1/2)\) phase, as shown in Figs. 1(g) and 1(h). The kagome and pinwheel phases have not been found to coexist. Note that \(x_s = 1/3 < 3/7 < 1/2\), the phase coexistence is thus natural if \(x_s = 3/7\) is the major stable phase between \(x_s = 1/3\) and 1/2. This is supported by our electrochemical Na de-intercalation study that shows a stable \(x \sim 3/7\) bulk phase does exist within a narrow surface potential range [20]. We caution that the inhomogeneity and nanoscale phase separation can lead to questionable interpretation of photoemission spectroscopy (PES) data [22]. For example, it was suggested that strong surface disorder can eliminate \(e'_g\) hole pockets that have so far evaded probing by PES [23]. Likewise, low-energy electron diffraction of Na ordering cannot be readily detected.

One immediate question is whether the Na trimer models are relevant in bulk crystals. STM cannot directly verify this issue. We wish, however, to suggest such relevance by showing that the trimer models can explain two unresolved bulk structure phase transitions in NaCoO₂. First, neutron powder diffraction reveals a first order structure transition between the so-called \(H1\) and \(H2\) phases for \(x \leq 0.75\) [24]. Na atoms occupy low symmetry \(6h\) \((2x, x, 1/4)\) sites at high temperatures (\(H1\) phase) while occupying high symmetry \(2c\) \((2/3, 1/3, 1/4)\) sites at low temperature (\(H2\) phase). In our trimer models, whether a trimer consists of all Na(2) or Na(1) atoms, or is O- or Co- centered, the Na atoms at Na(2) sites displace toward Na(1) sites, or vice versa. This places Na at the 6h sites and always leads to two shorter Na-O bonds and one longer Na-O bond, as observed in neutron studies [24,25]. In Ref. [24], the 6h Na...
higher in energy per formula unit (b) and (c) are respectively (a) is still the ground state at 0 K. Trimer structures (b) and (c) are respectively ~30 meV and ~40 meV higher in energy per formula unit (Na\textsubscript{1/3}CoO\textsubscript{2}). We thus postulate that Na trimers may be stabilized at finite temperature due to configuration entropy, in conjunction with the Na-O orbital energy reduction. As depicted in Figs. 2(a) and 2(b), an expanded trimer has multiple degrees of freedom to displace a Na(2) atom toward a Na(1) site [entropy gain ~k ln(2) per Na], or trimers can rotate around its center concertedly [entropy gain ~1/3 k ln(2) per Na]. Both lead to free energy reduction at T > 0 K. In contrast, the bulk (\sqrt{3} \times \sqrt{3}) phase could tolerate little disorder due to the lack of configuration entropy. We note that entropy-driven complex ordering has also been observed in some oxides [26].

In summary, we have discovered surprising Na trimer ordering on Na\textsubscript{2}CoO\textsubscript{3} surface with STM and proposed realistic structure models. The unexpected trimer stability and its relevance to bulk crystals are discussed. Future STM studies with fine Na concentration and temperature control can hopefully offer further microscopic details of this highly contended and intriguing material.
