An initial search with density functional theory to sort through potential cathode materials based on their Li intercalation potentials and electronic structures was carried out on LiNi$_{1/3}$TM$_{1/3}$TM$_{2/3}$O$_2$ systems, where TM1 is a 3$d^+$ transition metal (Co$^{3+}$, Al$^{3+}$, Fe$^{3+}$ etc.) and TM2 is a 4$d^+$ transition metal (Ti$^{4+}$, Zr$^{4+}$, Mn$^{4+}$ etc.). Substitution leads to a lower potential at the end of charge. Both X-ray photoelectron spectroscopy and first principles computer simulations indicate that Ni and Fe are simultaneously oxidized in this material. Computations further indicate that Co will be oxidized at the very end of charge. The LiNi$_{1/3}$Fe$_{1/6}$Co$_{1/6}$Mn$_{1/3}$O$_2$ compound synthesized at 750°C shows reversible capacity of 150 mAh/g with reasonably good capacity retention.

Lithium nickel manganese oxide and their derivatives are considered promising candidates for future lithium ion batteries. In a lower voltage range than Co$_3$O$_4$, the redox potential of Co$_3$O$_4$ can be lowered by substituting Co or Mn by other transition metals, which either bring down the redox potential or introduce another redox couple in the material. This is particularly useful in the negative electrode materials development, where further lowering of the redox potential can be achieved. The materials development involves synthesis, processing, characterization, and optimization. For each Li concentration, i.e., x = 1, 5/6, 2/3, 1/2, 1/3, and 0, respectively, all possible arrangements for Li and transition metals are fully considered.

Experimental.—Motivated by the first principles results, LiNi$_{1/3}$Fe$_{1/6}$Co$_{1/6}$Mn$_{1/3}$O$_2$ was synthesized by a sol-gel method using citric acid as a chelating agent. A stoichiometric amount of lithium acetate (Li(CH$_3$COO)$_2$·2H$_2$O), nickel acetate (Ni(CH$_3$COO)$_2$·4H$_2$O), cobalt nitrate (Co(NO$_3$)$_2$·6H$_2$O), iron nitrate (Fe(NO$_3$)$_3$·9H$_2$O) and manganese acetate (Mn(CH$_3$COO)$_2$·4H$_2$O) were used. As it is typical in solid state computations periodic boundary conditions are used, so that one can obtain a periodic system with Ni, Fe, Co, and Mn long-range ordered (Fig. 1). The effect of disorder, present in a real system, would likely smoothen the voltage curve from what is achieved computationally.

All energies, intercalation potentials, geometries, and electronic structure of materials in this paper were obtained using first-principles quantum mechanic calculations in the generalized gradient approximation (GGA) to DFT, as implemented in the Vienna ab initio simulation package (VASP). Ultrasoft pseudo-potentials are applied to represent the nuclei and core electrons and all structures are fully relaxed with respect to internal and external cell parameters. The wave functions are expanded in plane waves with energy below 405 eV. Brillouin zone integration of the band structure is performed using a 6 × 3 × 4 mesh. All calculations are performed with spin polarization, previously demonstrated to be crucial in manganese oxides. Both ferromagnetic and anti-ferromagnetic spin polarization were taken into consideration. For each Li concentration, the anti-ferromagnetic coupling among Ni, Mn, and Fe gives a lower energy than ferromagnetic coupling.

Partial states of delithiation were investigated at x = 5/6, 2/3, 1/2, 1/3, and 1/6. The number of possible arrangements for Li and vacant sites in the supercell are 1, 6, 15, 20, 15, 6, and 1 for x = 1, 5/6, 2/3, 1/2, 1/3, 1/6, and 0, respectively. All possible arrangements have been calculated.

$^*$ Electrochemical Society Active Member.
(Mn(CH\textsubscript{3}COO\textsubscript{2}).4\textsubscript{H}2O) were dissolved in distilled water and well mixed with aqueous solution of citric acid. The solution was stirred at 60-70°C for 5-6 h to obtain a clear viscous gel. The gel was dried in vacuum oven at 120°C for 24 h. The material was precalcined in two stages: at 350°C for 5 h and 450°C for 4 h, and then ground before calcining at high temperature (750-900°C) at a heating rate of about 2°C/min. The powders were slowly cooled to room temperature in oxygen.

Powder X-ray diffraction (XRD) data were collected on a Rigaku diffractometer with Cu K\alpha radiation (\lambda = 1.5406 \textsubscript{Å}), operating at 300 kV and 60 mA. To minimize the preferred orientation effect, typical in layered lithium intercalation compounds, Vaseline is mixed with sample powders to randomize the orientation of the particles. Grain morphology and particle size of LiNi\textsubscript{1/3}Fe\textsubscript{1/3}Co\textsubscript{1/3}Mn\textsubscript{1/3}O\textsubscript{2} compounds were examined by scanning electron microscopy using a JEOL FEG-6320.

Information of nickel, cobalt, iron and manganese oxidation states in pristine and electrochemically-charged samples were observed by XPS. Binding energies were charge-corrected using the C\textsubscript{1s} peak (285 eV).

LiNi\textsubscript{1/3}Fe\textsubscript{1/3}Co\textsubscript{1/3}Mn\textsubscript{1/3}O\textsubscript{2} electrodes were fabricated by mixing 85:1.5:3.5:10 (w/w) ratio of active material, SS carbon black, KS-6 carbon and polyvinylidene fluoride (PVDF), respectively, using N-Methyl-pyrrolidone (NMP) as the solvent. The resulting slurry was cast onto an aluminum current collector, dried under vacuum oven at 120°C for 4 h and put into an argon filled glove box for conditioning overnight. The electrode foils were roller-pressed to a uniform thickness of 100 \textmu m and then cut into disks of 10 mm diam.

Electrochemical measurements were made using coin-type cells comprising Li metal counter electrode with a 1 M solution of LiPF\textsubscript{6} in EC/DMC (1:1 v/v, Merck LP30) as the electrolyte. The cells were assembled in the argon filled glove box where both moisture and oxygen levels are less than 1 ppm. The cells were charged and discharged using a Maccor battery tester at a C/10 rate.

Results and Discussion

First principles study of Co/Mn substitution.—An initial search on LiNi\textsubscript{1/3}TM\textsubscript{1/3}TM\textsubscript{2/3}O\textsubscript{2}, where TM1 = Al\textsuperscript{3+}, Ti\textsuperscript{4+}, Fe\textsuperscript{3+}, or Zr\textsuperscript{4+} and TM2 = Mn\textsuperscript{4+}, Ni\textsuperscript{2+}, or Co\textsuperscript{2+} end of charge. In agreement with previous work on Al-doping, substitution of Co by Al increases the potential. As it cannot be oxidized beyond 3+, Al doping also reduces the capacity at the end of charge. Of all the compositional modifications investigated, Fe substitution of Co seems to be advantageous because it lowers the voltage profile at the last stage of the charge, compared to LiNi\textsubscript{1/3}Co\textsubscript{1/3}Mn\textsubscript{1/3}O\textsubscript{2}. Hence, the specific capacity of LiNi\textsubscript{1/3}Fe\textsubscript{1/3}Mn\textsubscript{1/3}O\textsubscript{2} could be higher in the potential window of 3.0-4.5 V.

It is well known that due to the similar ion size of Fe\textsuperscript{3+} and Li\textsuperscript{+}, the Fe can partially occupy the Li-layer. In addition, unlike LiCoO\textsubscript{2} and LiNiO\textsubscript{2}, the LiFeO\textsubscript{2} ground-state structure is not layered, but a structure with symmetry I\textsubscript{4}1/amd. According to our preliminary mixing enthalpy calculations using the equation below, the relative formation energy of LiNi\textsubscript{1/3}Fe\textsubscript{1/3}Mn\textsubscript{1/3}O\textsubscript{2} with respect to LiNi\textsubscript{1/3}Fe\textsubscript{1/3}Mn\textsubscript{1/3}O\textsubscript{2} and LiFeO\textsubscript{2} is approximately zero, indicating that only a weak entropic driving force for mixing might exist in a compound where Co is fully substituted by Fe.

\[
\Delta E_{\text{mix}} = E_{\text{LiNi}_{1/3}\text{Fe}_{1/3}\text{Co}_{1/3}\text{Mn}_{1/3}\text{O}_2} - [2/3E_{\text{LiNi}_{1/3}\text{Fe}_{1/3}\text{O}_2} + zE_{\text{LiFeO}_2} + (1/3 - z)E_{\text{LiCoO}_2}]
\]

Therefore, we chose to substitute Co only partially by Fe and targeted the nominal composition LiNi\textsubscript{1/3}Fe\textsubscript{1/3}Co\textsubscript{1/3}Mn\textsubscript{1/3}O\textsubscript{2} to obtain pure single-phase layered material.

Synthesis and characterization of as-prepared material.—The structure of the LiNi\textsubscript{1/3}Fe\textsubscript{1/3}Co\textsubscript{1/3}Mn\textsubscript{1/3}O\textsubscript{2} powders synthesized by sintering at 750, 800, and 850°C for 16 h were characterized using XRD (Cu K\alpha radiation), as shown in Fig. 3. XRD spectra show that all as-prepared samples have the α-NaFeO\textsubscript{2} type layered structure with space group R3\textsubscript{m}. The two small peaks between 20 and 25° are from Vaseline added to the sample. The region around the (104) reflection in the XRD spectra is shown in Fig. 3b. For powders synthesized at 750°C the (104) peak is broadened, indicating a small grain size, which was further confirmed by scanning electron microscopy (SEM) (Fig. 4a). For powders synthesized at 850°C an extra peak right beside the (104) peak (see Fig. 3b) starts to evolve. We suspect that this peak is related to the formation of a cation-disordered rock-salt structure. The clear splitting of the reflections assigned to the Miller indices (006, 102) and (108, 110) in the XRD spectrum of the 750 and 800°C sample indicates a well-layered structure.
The lattice parameters $a$ and $c$, determined from the sample synthesized at 750°C, are 2.8854 and 14.3221 Å, respectively. The calculated lattice parameters are 2.9138 and 14.3690 Å, which are slightly larger than those measured, as is often the case for computations in the generalized gradient approximation. In LiNi$_{1/3}$Co$_{1/3}$Mn$_{1/3}$O$_2$ synthesized at 900°C by the same sol-gel method, $a$ and $c$ are 2.864 and 14.247 Å, respectively. 6 The larger $a$ and $c$ lattice parameters of LiNi$_{1/3}$Fe$_{1/6}$Co$_{1/6}$Mn$_{1/3}$O$_2$ can be explained by the larger ion size of Fe$^{III}$ as compared to Co$^{III}$.

A comparison of SEM micrographs obtained for LiNi$_{1/3}$Fe$_{1/6}$Co$_{1/6}$Mn$_{1/3}$O$_2$ synthesized at 750, 800, and 850°C is shown in Fig. 4. All samples have a uniform grain size and faceted grain morphology. The grains grow from 40-50 nm at 750°C to 300-500 nm at 850°C.

**Intercalation potential.**—Average voltage profiles for Li$_{x}$Ni$_{1/3}$Fe$_{1/6}$Co$_{1/6}$Mn$_{1/3}$O$_2$ ($0 \leq x \leq 1$) were computed from the lowest energy lithium-vacancy arrangements in the six-formula supercell as function of lithium compositions. The calculated potentials are typically lower than experimental values, as is usually the case in standard first principles energy methods.4,16 The calculated intercalation voltage of Li$_{x}$Ni$_{1/3}$Fe$_{1/6}$Co$_{1/6}$Mn$_{1/3}$O$_2$ is compared to that of Li$_{x}$Ni$_{1/3}$Co$_{1/3}$Mn$_{1/3}$O$_2$ in Fig. 5. In the range $1/3 \leq x \leq 1$, a calculated average voltage of 3.0-3.1 V is obtained for Li$_{x}$Ni$_{1/3}$Fe$_{1/6}$Co$_{1/6}$Mn$_{1/3}$O$_2$. The potential increases significantly to 3.8-3.9 V in the range $0 \leq x \leq 1/3$. Compared to Li$_{x}$Ni$_{1/3}$Fe$_{1/6}$Co$_{1/6}$Mn$_{1/3}$O$_2$, the substitution of Fe with Co increases the average voltage slightly for $1/2 \leq x \leq 1$. Most importantly, in the Fe substituted compound, the calculated voltage at the end of charge ($0 \leq x \leq 1/3$) is much lower than that of Li$_{x}$Ni$_{1/3}$Co$_{1/3}$Mn$_{1/3}$O$_2$. These results indicate that Fe substitution of Co in Li$_{x}$Ni$_{1/3}$Fe$_{1/6}$Co$_{1/6}$Mn$_{1/3}$O$_2$ may flatten the voltage curve and increase the experimentally attainable capacity by lowering the potential near the end of charge.

**Electrochemical characterization.**—Electrodes of LiNi$_{1/3}$Fe$_{1/6}$Co$_{1/6}$Mn$_{1/3}$O$_2$ synthesized at 750, 800, and 850°C were cycled at a rate of C/10 based on 281 mAh/g total capacity between 3.0 and 4.5 V. The first charge and discharge curves for each sample are shown in Fig. 6. Qualitatively, the potential curves are very similar, exhibiting a relatively flat potential on charging in the range of 3.7 to 3.9 V, and then a relatively steeply sloping curve on discharge. The compound synthesized at 750°C shows smaller polarization which could be related to its smaller grain size. There is a significant amount of irreversible capacity after the first charge for all three samples. As the synthesis temperature increases from 750, 800, to 850°C, the first charge capacity decreases from 220 to 200-187 mAh/g, the first discharge capacity changes from 150 to 139-134 mAh/g. The capacity retention up to 30 cycles is reasonably good for all samples, as demonstrated in Fig. 7. The reason for the large first-cycle irreversible capacity is currently being investigated. A preliminary study shows that the first cycle reversible capacity can be increased by 20% with surface treatment of the synthesized powders.

The delithiation potential of the material synthesized at 750°C is plotted together with the calculated potential curve. The potential difference between the calculated and experimental data is suggested to be 0.7-0.8 V.16 The correction of 0.9 V in this case was
added to the calculated potential to display a result that can be compared directly with the experimental values, as shown in Fig. 8. The experimental charge-discharge curve matches the calculated one well in the range of \( \frac{1}{3} < x < 1 \). The practical specific capacity of this material will likely be more than 250 mAh/g if the cell is charged to approximately 4.8 V, according to the computational prediction.

**Electronic change during charge-discharge.**—To understand the electronic changes in LiNi_{1/3}Fe_{1/6}Co_{1/6}Mn_{1/3}O_2 when lithium is removed, the spin polarized density of states (DOS) at different lithium concentrations is shown in Fig. 9. Because the transition metal ions occupy the octahedral sites in the sublattices of oxygen ions, 3d bands of transition metal ions split into \( t_{2g} \) and \( e_g \) bands. The calculated DOS, projected onto the orbitals of each transition metal are shown in Fig. 9.

For all lithium compositions, the Mn-\( t_{2g} \) and Mn-\( e_g \) bands, respectively, half filled and empty in Li_{1-x}Ni_{1/3}Fe_{1/6}Co_{1/6}Mn_{1/3}O_2 (0 \leq x \leq 1), which is consistent with a Mn^{4+} valence state. For fully lithiated LiNi_{1/3}Fe_{1/6}Co_{1/6}Mn_{1/3}O_2 (x = 1 in Fig. 9a), Ni-\( t_{2g} \) states are fully occupied and only one spin direction for the Ni-\( e_g \) states is occupied. For Fe-\( t_{2g} \) and Fe-\( e_g \), only the majority spin states are occupied indicating high-spin Fe^{3+}. The Co-\( t_{2g} \) states are fully occupied and Co-\( e_g \) states are empty, indicative of Co^{3+}. The Fermi level, \( E_F \), is located between the top of occupied Co-\( t_{2g} \) bands and unoccupied Fe-\( t_{2g} \) states. There is an energy gap of about 0.3 eV between the unoccupied and occupied states. Although it is well know that the calculated energy gaps in GGA are typically smaller than the experimental values, the comparison with the calculated energy gap for LiNi_{1/3}Co_{1/3}Mn_{1/3}O_2 (0.7 V)\(^6\) indicates that the electronic conductivity of LiNi_{1/3}Fe_{1/6}Co_{1/6}Mn_{1/3}O_2 may be as good, if not better, as LiNi_{1/3}Co_{1/3}Mn_{1/3}O_2.

As we applied a supercell with six-formula units in this study, both Ni^{2+}/Ni^{3+} and Ni^{2+}/Ni^{4+} are possible redox reactions. Figure 9a and b show that for a partially delithiated state (2/3 \leq x \leq 1), only the Ni^{3+}/Ni^{4+} redox reaction is observed, which is consistent with the previous studies on LiNi_{1/2}Mn_{1/2}O_2 and LiNi_{1/3}Co_{1/3}Mn_{1/3}O_2.\(^6,17,18\) At x = 2/3 (Fig. 9b), there is an overlap between filled Ni-\( e_g \) and Fe-\( e_g \) states, indicating very similar redox potentials for Ni and Fe ions. Electrons are simultaneously removed from the Ni-\( e_g \) and Fe-\( e_g \) bands upon further delithiation as shown in Fig. 9c. It clearly indicates that the Ni^{3+}/Ni^{4+} and Fe^{3+}/Fe^{4+} redox reactions take place simultaneously. Such simultaneous redox reactions of Fe and Ni have been reported in the Li(Ni,Fe)O_2 system by

**Figure 5.** Comparison of calculated average voltage curves of LiNi_{1/3}Co_{1/3}Mn_{1/3}O_2 and LiNi_{1/3}Fe_{1/6}Co_{1/6}Mn_{1/3}O_2.

**Figure 6.** Comparison of first charge-discharge curves of the LiNi_{1/3}Fe_{1/6}Co_{1/6}Mn_{1/3}O_2 materials synthesized at 750, 800, and 850°C for 16 h.

**Figure 7.** Charge and discharge capacity vs. cycle number curves of the LiNi_{1/3}Fe_{1/6}Co_{1/6}Mn_{1/3}O_2 materials synthesized at 750, 800, and 850°C for 16 h.

**Figure 8.** Comparison of experimental potential curve (sample synthesized at 750°C) with the predicted potential curve by first principles calculation.
Fe Mossbauer and extended X-ray absorption fine structure (EXAFS) investigations. Furthermore, upon delithiation (1/3 < x < 2/3), the Fe-eg states become empty and all four valence electrons partially fill Fe-t2g states indicating low-spin for Fe3+. At x = 0, an electron is also pulled from the Co-t2g band (Fig. 9d), which demonstrates that the redox couple Co3+/Co4+ is activated at the end of charge.

XPS was applied to corroborate the electronic behavior predicted computationally. Ex situ XPS study was carried out to study the valence shifts of Ni, Co, Fe, and Mn in LiNi0.33Fe0.17Co0.17Mn0.33O2 and in partially charged LiNi0.33Fe0.17Co0.17Mn0.33O2 (x ∼ 1/2). The electrodes were charged to 4.4 V. The binding energies of those cations in the as-prepared and partially charged compounds are tabulated in Table I. Indicating by the binding energy shift of the 2p electrons for the transition metal cations from their elemental values, XPS confirms that the valence states of Ni, Fe, Co, and Mn in the as-synthesized LiNi0.33Fe0.17Co0.17Mn0.33O2 are 2+, 3+, 3+, and 4+, respectively. Furthermore, as lithium is removed from the compound, both Ni2+/Ni3+/Ni4+ and Fe3+/Fe4+ redox couples are activated, revealed by an obvious shift in binding energies of Ni 2p and Fe 2p edges. No obvious shifts in Co and Mn edges were observed. The results are in good agreement with the calculated change of valence states during delithiation.

Number in the parentheses—shift in binding energy.
There is no significant difference in the structural parameters among different lithium-vacancy configurations at the same composition.

The calculated lattice parameter decreases in the range of $1/3 \leq x \leq 1$ by approximately 2.2% and increases slightly in the range of $0 \leq x \leq 1/3$. The lattice parameter $c$ increases by about 4.2% in the range of $1/3 \leq x \leq 1$ and decreases for $0 \leq x \leq 1/3$. The maximum change in cell volume is only 1.6%, which implies that effect of stress and strain in the material during the lithiation-delithiation cycle will be very small. In comparison the volume change of LiCoO$_2$ is about 3 to 4 percent.$^{20}$

The average bond distances between the transition metal ions and oxygen ions at different lithium contents are plotted in Fig. 11. The bond distances of Ni-O and Mn-O in fully lithiated Li$_x$Ni$_{1/3}$Fe$_{1/6}$Co$_{1/6}$Mn$_{1/3}$O$_2$ material ($x = 1$) are [2.04 2.05 2 × 2.06 2.07] Å, [2.06 2.07 2.08 3 × 2.09] Å, and [1.93 4 × 1.94 1.95] Å, respectively. The bond distance of Ni-O is much longer than that of Mn-O, indicating Ni has oxidation state of $2+$ in this material. Fe-O has similar bond distances as Ni-O [2.04 4 × 2.05 2.06] Å, which can be explained by the similar size of Fe$^{3+}$ and Ni$^{3+}$ [Shannon radius].$^{21}$ Co-O has the typical bond distance of Co$^{3+}$ in the layered compound.$^{22}$

As lithium is removed, in the range of $2/3 \leq x \leq 1$, Ni$^{2+}$ is oxidized and the bond distances of Ni-O become shorter. The large spread of bond lengths for Ni-O in this range is due to Jahn-Teller distortion of Ni$^{3+}$O$_6$ octahedron. Note that this also affects the Fe-O and Mn-O bond lengths. Such distortion disappears upon further lithium removal: in the range of $1/3 \leq x \leq 2/3$, the Fe-O (Fig. 11c) and Ni-O (Fig. 11a and b) bond distances reduce simultaneously, which is in good agreement with the DOS observations in Fig. 9. In addition, in this range ($1/3 \leq x \leq 2/3$) the decrease in Fe-O bonds distance changes the crystal field splitting between the $e_g$ and $t_{2g}$ bands,$^{23}$ which leads to low-spin of Fe$^{3+}$, as mentioned previously.

Conclusions

Motivated by a series of first principles calculations on LiNi$_{1/3}$Co$_{1/3}$Mn$_{1/3}$O$_2$ with Co or Mn substituted by other metals, LiNi$_{1/3}$Fe$_{1/6}$Co$_{1/6}$Mn$_{1/3}$O$_2$ was synthesized by a sol-gel method. We

predicted and confirmed that Fe substitution would lead to a lower potential at the end of charge. Both XPS and first principles electronic structure computations indicate that Ni and Fe are simultaneously oxidized in this material. Computations further indicate that Co will only be oxidized at the very end of charge. The LiNi_{1/3}Fe_{1/6}Co_{1/6}Mn_{1/3}O_2 compound synthesized at 750°C shows reversible capacity of 150 mAh/g with reasonably good capacity retention. In this work, we have demonstrated that an integrated approach of computation and experiment has produced a new electrode material with very few iteration steps in the material design cycle. We believe that such direct integration of ab-initio methods with experimental research holds promise for significantly shortening the development cycle of materials.
