ABSTRACT: First principles computation is carried out for investigating the electronic, structural, and electrochemical properties of LiM<sub>x</sub>Mn<sub>3/2</sub>O<sub>4</sub> (M = Ti, V, Cr, Fe, Co, Ni, and Cu). The computation results suggest that doping with Co or Cu can potentially lower Li diffusion barrier as compared to Ni doping. Our experimental research has focused on LiNi<sub>x</sub>Cu<sub>y</sub>Mn<sub>2−x−y</sub>O<sub>4</sub> (0 < x < 0.5, 0 < y < 0.5), and we found that the amount of Cu will affect the lattice parameters, the cation disorder in the spinel lattice, the particle morphology, as well as the electrochemical properties. Crystal structures, electronic structures, and electrochemical properties of LiNi<sub>x</sub>Cu<sub>y</sub>Mn<sub>2−x−y</sub>O<sub>4</sub> (0 < x < 0.5, 0 < y < 0.5) are studied by X-ray diffraction (XRD), scanning electron microscopy (SEM), X-ray absorption spectroscopy (XAS), and electrochemical measurements including potentiostatic intermittent titration technique (PITT). With detailed electrochemical measurements and in situ XAS experiments of LiNi<sub>x</sub>Cu<sub>y</sub>Mn<sub>2−x−y</sub>O<sub>4</sub>, the proposed explanation of the voltage profile by the first principles computation was proven, a second plateau at 4.2 V originates from the oxidation of Cu<sup>2+</sup> to Cu<sup>3+</sup>, and the plateau at 4.95 V may originate from extra electrons provided by oxygen ions. Although the reversible discharge capacity decreases with increasing Cu amount, optimized composition such as LiCu<sub>0.25</sub>Ni0.25Mn1.50O4 exhibits high capacities at high rates.

KEYWORDS: first principles computation, high-voltage spinel, Li-ion batteries

INTRODUCTION

LiMn<sub>2</sub>O<sub>4</sub> spinel is an attractive compound as a cathode material in lithium-ion batteries, due to its economical, environment, and safety advantages over LiCoO<sub>2</sub>. LiMn<sub>2</sub>O<sub>4</sub> adopts the spinel structure with the space group Fd<sub>3</sub>m, in which the Li and Mn occupy the 8a tetrahedral and 16d octahedral sites of the cubic close-packed oxygen ions framework, respectively. However, LiMn<sub>2</sub>O<sub>4</sub> tends to exhibit capacity fade in the 4 V region, particularly at elevated temperatures. Factors such as Mn dissolution into the electrolyte and the development of microstrains<sup>1,2</sup> during cycling have been suggested to be the main sources of capacity fade. The poor cycling performance could be improved by partial substitution of Mn with other metals, an approach to making the LiM<sub>x</sub>Mn<sub>2−x</sub>O<sub>4</sub> (M = Co, Mg, Cr, Ni, Fe, Al, Ti, Cu, Zn, etc.) electrode material.<sup>3–7</sup> It has been found that a higher voltage plateau (>4 V) accompanies some transition metal doping.<sup>5</sup> Among all LiM<sub>x</sub>Mn<sub>2−x</sub>O<sub>4</sub> materials, LiNi<sub>0.5</sub>Mn<sub>1.5</sub>O<sub>4</sub> is an attractive high voltage cathode material because it offers a flat voltage plateau at 4.7 V and demonstrates a reversible capacity >135 mAh/g.<sup>6,7</sup> Several strategies were developed to improve the rate capability of LiNi<sub>0.5</sub>Mn<sub>1.5</sub>O<sub>4</sub>. Arrebola et al. obtained excellent rate properties by homogeneously mixing nano- and micro-size LiNi<sub>x</sub>Mn<sub>1−x</sub>O<sub>4</sub> powders,<sup>8</sup> or by adding polyethylene glycol (PEG) to increase the crystallinity and decrease the strain.<sup>9</sup> The rate capability was also affected by the atomistic structure of the spinel material, as proposed by Kunduraci et al..<sup>10</sup> It is found that nonstoichiometric LiNi<sub>x</sub>Mn<sub>1−x</sub>O<sub>4</sub> (Fd<sub>3</sub>m) exhibited better structural reversibility at high rate as compared to stoichiometric LiNi<sub>x</sub>Mn<sub>1.5</sub>O<sub>4</sub> (P<sub>4</sub>32). The oxygen deficiency leads to the presence of a small amount of Mn<sup>1+</sup> in the pristine materials, which leads to better electronic conductivities in the material. The Cu-doped spinel materials were investigated by a few research groups.<sup>11–14</sup> Although the Cu-rich spinel electrodes provide lower discharge capacity than Ni-rich spinel electrodes, it is more stable during electrochemical cycling. Moreover, LiCu<sub>δ</sub>Mn<sub>2−δ</sub>O<sub>4</sub> has a higher electronic conductivity than do other spinel LiM<sub>x</sub>Mn<sub>2−x</sub>O<sub>4</sub> materials (Cr, Fe, Co, Ni),<sup>15</sup> because Cu can participate in the...
charge transport process. All of the previous work focused mainly on the electronic conductivity in the doped spinel LiM₃Mn₂₋ₓO₄ materials. Little has been explored to enhance the lithium ionic diffusivity in this family of materials. Using ab initio computational modeling, it is possible to rapidly screen the effect of different doping elements on the lithium diffusion activation barrier, as well as the redox potentials in the spinel structure. Ab initio computational method was first used by Van der Ven et al. to determine the energy barrier of Li diffusion in layered transition metal oxides.¹⁶ Kang et al. also used this method to identify the factors that limit Li⁺ ion hopping in layered oxide and successfully synthesize an optimized layered material with superior rate capability.¹⁷

Many researchers have already shown that the cycling performance of LiNi₀.₅Mn₁.₅O₄ can be improved by doping with different transition metal ions.¹⁸–²¹ However, a systematic understanding of the effects of co-doped elements is still lacking. In this work, first principles computation, based on density functional theory (DFT), is used to examine the voltage profile and electronic structures of the LiM₃Mn₂₋ₓO₄ (M = Ti, V, Cr, Fe, Co, Ni, Cu). The Li diffusion activation barriers in each material are calculated and compared. On the basis of the computational prescreening, our experimental research focuses on LiNi₀.₅Mn₁.₅₋ₓO₄ (0 < x < 0.₅, 0 < y < 0.₅), which have the potential to achieve high voltage, high rate, and good cycling performance, while keeping relatively high capacity. The materials with different Cu/Ni concentrations are synthesized using the sol–gel process. Their crystal structures, electronic structures, and electrochemical properties are then characterized and studied experimentally.

### COMPUTATIONAL METHODS

In this work, a supercell composed of eight formula units of LiₓM₃₋ₓMnₓ/₂O₄ (M = Ti, V, Cr, Fe, Co, Ni, and Cu) is used. The doped spinel with ordered cation arrangement belongs to the space group P4₃2₁. Ox ions occupy the 8c and 24e sites, forming a close-packed fcc lattice. Mn ions occupy the 12d octahedral sites, while M ions occupy the 4b octahedral sites. The 8c tetrahedral sites are filled with Li ions. For LiₓCuₓ₋₁Mnₓ₂₋ₓO₄, an additional model of Cu ions exchanging sites with one-half of the Li ions was built and investigated. Calculations were performed using density functional theory (DFT) in the spin-polarized generalized gradient approximation (GGA) and in the GGA with Hubbard U correction (GGA+U). Core electron states were represented by the projector augmented-wave method²² as implemented in the Perdew–Burke–Ernzerhof exchange correlation.²⁶ A plane wave representation for the wave function with a cutoff energy of 370 eV were used. The Brillouin zone was sampled with a 5 × 5 × 5 mesh by Gamma packing. The atomic positions and cell parameters are fully relaxed to obtain total energy and optimized cell structure. To obtain the accurate electronic density of states (DOS), a static self-consistent calculation was run, followed by a non-self-consistent calculation using the calculated charge densities from the first step. The cell volume was fixed with internal relaxation of the ions in the second step calculation. A supercell with one vacancy out of eight Li sites (LiₓM₃₋ₓMnₓO₄) was used to calculate the Li diffusion activation barriers in the Li-rich phase with GGA approximation. The Hubbard U correction was introduced to describe the effect of localized d electrons of transition metal ions when investigating the valence states and electronic structures of the ions. Previous work has shown that the U values can be calculated in a self-consistent way and the U values of Mn and Ni ions in the spinel structure are well established.²⁷–²⁹ These values are taken as the references. In the doped spinel system, the same transition metal ions with different valence states may coexist; therefore, small adjustments are made to the reference U values, so that each transition metal ion has a unique effective U value applied in the rotationally invariant LSDA+U approach. In this work, the applied effective U value given to Mn ions is 5 eV, to Ni ions is 5.96 eV, and to Cu ions is 7 eV.

### EXPERIMENTAL METHODS

#### Sample Preparation.
Six samples were synthesized using the sol–gel method: LiNi₀.₅Mn₁.₅₋ₓO₄, LiNi₀.₄₅Mn₁.₅₅₋ₓO₄, LiCu₀.₀₅Ni₀.₄₅Mn₁.₅₋ₓO₄, LiCu₀.₂₅Ni₀.₂₅Mn₁.₅₋ₓO₄, and LiCu₀.₅Ni₀.₁Mn₁.₅₋ₓO₄. The sol solutions were prepared from the stoichiometric mixtures of Li(CH₃COO)₂·2H₂O (Fisher), Ni(CH₃COO)₂·4H₂O (Fisher), Cu(CH₃COO)₂·H₂O (Fisher), and Mn(CH₃COO)₂·4H₂O (Fisher) in distilled water. Next, the solution was added dropwise to a continuously stirred aqueous solution of citric acid. The pH of the mixed solution was adjusted to 6.5 by adding an ammonium hydroxide solution. The solution was then heated at 75°C overnight; a transparent gel was obtained. The resulting gel precursors were decomposed at 450°C for 10 h in air and calcined at 800°C for 10 h.

#### X-ray Diffraction.
Powder diffractions of all samples were collected using a high-resolution synchrotron powder X-ray diffractometer at beamline 11–BM at the Advanced Photon Source (APS), Argonne National Laboratory (U.S.). The conditions for the data collection were continuous scanning of a detector covering an angular range from 0.₅° to 40° with a step size of 0.₀₀₀₁° and wavelengths of λ = 0.₄₁₃₉₆₄ Å. The diffraction patterns were analyzed by the Rietveld refinement software, FullProf.³¹ The ex situ XRD data were collected by a laboratory X-ray diffractometer equipped with a curved position sensitive detector (Inel CPS120, detection range 0–120°), a Cu X-ray tube source, and a Gobel mirror on the incident beam. The collection time for each XRD spectrum was 20 min. The samples for ex situ XRD were recovered by disassembling cycled batteries in an argon-filled glovebox, and the powder mixture was scraped from the aluminum disks.

#### ICP-AES.
The chemical compositions of the samples were analyzed by inductive coupled plasma atomic emission spectroscopy (ICP–AES Perkin-Elmer Plasma 3200). The instrument is equipped with two monochromators covering the spectral range of 167–785 nm with a grating ruling of 3600 lines/mm. The system is capable of analyzing materials in both organic and aqueous matrices with a detection limit range of less than 1 ppm. The instrument was initially calibrated using commercial LiCoO₂ and LiFePO₄ powders.

#### SEM.
Field emission secondary electron microscopy (PEG-SEM, JEOL JSM-6335F) was carried out to investigate the particle size and morphologies. Images were collected with an accelerating voltage of 15 kV.

#### In Situ XAS.
X-ray absorption spectroscopy (XAS) at the Ni, Mn, and Cu K-edges was obtained in transmission mode at the National Synchrotron Radiation Research Center (NSRRC), Hsinchu, Taiwan, to observe the changes in nickel, manganese, and copper oxidation states for LiCu₀.₂₅Ni₀.₂₅Mn₁.₅₋ₓO₄ during the charging process. A Si (111) double crystal monochromator was employed for energy selection. The coin cell 2016 was charged to target voltage (4.₁ V–5 V) and rested for 40 min (10 min to reach equilibrium, 30 min to get spectrum) to obtain the spectroscopy. The spectrum was collected every 0.₁ V.

#### Electrochemistry.
The electrochemical properties of all cathode electrodes were measured using 2016 coin cells consisting of metallic lithium as an anode and an electrolyte comprised of 1 M LiPF₆ in a 1:1 volume fraction of ethylene carbonate (EC)/dimethyl carbonate (DMC). Celgard model C480 separator (Celgard Inc., U.S.) was used as separator. Cathode films were prepared from slurries of LiCu₀.₀₅Ni₀.₄₅Mn₁.₅₋ₓO₄ with 7.₅% polyvinylidene fluoride (PVDF) and 7.₅% acetylene carbon black dissolved in N-methyl-2-pyrrolidinone (NMP).
The mixtures were cast onto Al foil using a doctor blade and dried at 100 °C overnight. Electrode discs were cut into cathodes containing 5–10 mg of active materials before storing them in an argon-filled glovebox. To measure the chemical diffusion coefficient, the potentiostatic intermittent titration technique (PITT) was performed by applying a voltage step of 10 mV. The potential was stepped to the next level when the current decreased below 3 x 10 μA (which is equivalent to C/200 rate). The voltage window was set from 4.5 to 4.9 V.

## RESULTS AND DISCUSSION

**First Principles Calculations.** Previous research has shown that, when Li ions diffuse in the undoped LiMn2O4 spinel structure, the diffusion activation barriers are reached when Li ions occupy the intermediate 16c sites, which are surrounded by six Mn ions forming a Mn ring.29 A similar situation occurs in the doped spinel LiM1/2Mn3/2O4 (M = Ti, V, Cr, Fe, Co, Ni, and Cu); however, the rings are now composed of two types of metal ions: Mn and the doped transition metal ion M. In the supercell used for this work, for each dopant, two distinct local environments of transition metal ion rings can be found. One is composed of three doped M ions and three Mn ions alternatively arranged (Figure 1a). The other one is composed of one doped M ion and five Mn ions (Figure 1b). The corresponding Li diffusion barriers with different dopants (M = Ti, V, Cr, Fe, Co, Ni, and Cu) are calculated using the GGA method (Figure 2). The Li diffusion barrier in undoped Mn spinel129 is also provided as the reference. As compared to the undoped Mn spinel material, the average Li diffusion barrier remains largely unchanged when Ni and Fe ions are present. The average diffusion barrier increases with Ti, V, Cr doping and decreases with Co and Cu doping. Specifically, when only one Cu or three Co ions appears in the ring, the Li diffusion barrier can be reduced to as low as 256 meV, respectively.

As was shown in previous work,29 the introduction of the Hubbard U correction accurately captures the charge/discharge voltages of the Li-intercalation spinel materials. More importantly, different valence states of the same transition metal ions can be distinguished. Calculations using the GGA+U method are performed on LiCu1/2Mn1/2O4 spinel with different Li concentrations. In the first model, where Cu ions occupy 4b octahedral sites and Li ions occupy 8c tetrahedral sites, the calculated average voltage of LiCu1/2Mn1/2O4 (0.5 < x < 1) is 4.44 V, which is 7% higher than the experimental low voltage plateau. In addition, the calculated average voltage of LiCu1/2Mn1/2O4 (0 < x < 0.5) is 5.36 V, which is 9% higher than the experimental high voltage plateau. The projected electronic density of states (DOS) of Cu 3d orbitals in LiCu1/2Mn1/2O4 (x = 1, 1/2, 0) are calculated and presented in Figure 3a–c, respectively. In the proposed spinel model, the octahedral crystal field splits the Cu 3d orbitals into two parts. dxy, dxz, and dyz orbitals belong to the t2g orbitals with lower energy levels, while d2, dx2−y2 belong to the eg orbitals with a higher energy level.32 Figure 3a shows the projected DOS of Cu ions in the fully lithiated phase LiCu1/2Mn1/2O4. Both spin-up and spin-down states of the three t2g orbitals are below the Fermi energy, which means the t2g orbitals are completely occupied. For eg orbitals, the d2 orbital is occupied, but the spin-up state of the d2−y2 orbital is above the Fermi energy, indicating that the d2−y2 orbital is half empty. The DOS plot is consistent with the t2g eg electron configuration of Cu2+ ions. The projected DOS of Cu ions in the half-delithiated phase Li1/2Cu1/2Mn1/2O4 (Figure 3b) and in the fully delithiated phase Cu1/2Mn1/2O4 (Figure 3c) are generally the same minus trivial differences in shape. It suggests that Cu ions are in the same valence state in the two compositions. The spin-up states of the eg orbitals are completely empty, while all of the other electronic states are occupied. The DOS plots indicate the electron configuration of t2g eg consistent with Cu3+ ions. On the basis of these results from first-principles calculation, the Cu valence in doped spinel LiCu1/2Mn1/2O4 is Cu2+ at fully lithiated state. The Cu2+ ions can be oxidized to Cu3+ when one-half of the Li ions are extracted. Valence higher than 3+ cannot be obtained, and the calculated voltage of the Cu3+/Cu2+ redox couple is 4.44 V. When more than one-half of the Li ions are extracted, the charge densities of oxygen ions change significantly, suggesting that the extra electrons may be provided by oxygen ions.

If one exchanges the sites of Cu ions with one-half of the Li ions, a defect spinel model can be created with tetrahedral Cu and octahedral Li included. For the defect spinel system, its total energy is 493 meV per formula higher than the perfect spinel system, and therefore the structure should be thermodynamically less stable. However, the experimental synthesis is often conducted at relatively high temperatures (>700 °C), and a certain amount of transition metal and lithium ion site mixing occurs. The change of Cu valence versus Li concentration is investigated.
using a method similar to that described above. Tetrahedral Cu\(^{2+}\) can also be oxidized to Cu\(^{3+}\), but no higher valence can be obtained. In the defect spinel model, Li ions in octahedral sites are preferred to be extracted first, and the calculated voltage is 4.58 V. The calculated voltage step for removing the remaining tetrahedral Li is 4.99 V, a surprisingly high value.

As compared to the NiMn spinel LiNi\(_{1/2}\)Mn\(_{3/2}\)O\(_4\), in which Ni\(^{2+}\) can be oxidized to Ni\(^{4+}\) providing two electrons per ion, the reversible capacity of Cu doped spinel may be reduced as Cu ions can only provide one electron per ion. However, when doped with a small amount of Cu, it is possible to lower the Li diffusion activation barriers so that better rate capability can be obtained. To further understand the crystal structure, electronic structure, and electrochemical properties in a new series of bidopant spinel materials, we successfully synthesized and studied the LiNi\(_x\)Cu\(_y\)Mn\(_{2-x-y}\)O\(_4\) with different amount of dopants (\(x = 0, 0.05, 0.10, 0.25, \) and 0.5).

**Chemical Composition Analysis.** The atomic compositions of LiNi\(_x\)Cu\(_y\)Mn\(_{2-x-y}\)O\(_4\) electrode materials calcinated at 800 °C were obtained from ICP-AES analysis. Although a nickel oxide and a copper oxide impurity phase appear, respectively, in LiNi\(_{0.5}\)Mn\(_{1.5}\)O\(_4\) and LiCu\(_{0.5}\)Mn\(_{1.5}\)O\(_4\) samples, the molar ratio of Li, Ni, and Mn is in good agreement with the theoretical ratio of all samples.

**X-ray Diffraction of LiNi\(_x\)Cu\(_y\)Mn\(_{2-x-y}\)O\(_4\).** X-ray diffraction patterns for LiNi\(_x\)Cu\(_y\)Mn\(_{2-x-y}\)O\(_4\) are depicted in Figure 4. Detailed Rietveld refinement fitting results of LiNi\(_x\)Cu\(_y\)Mn\(_{2-x-y}\)O\(_4\) are shown in the Supporting Information (Figures S1–S6). The spinel structure with space group Fd\(_{3}m\) can be identified according to the indexed major peaks. In some samples, small amounts of impurities are present, such as nickel oxide in LiNi\(_{0.5}\)Mn\(_{1.5}\)O\(_4\) and copper oxide in LiCu\(_{0.5}\)Mn\(_{1.5}\)O\(_4\) as shown in the inset in Figure 4. The impurities may be tied with the solubility limit of nickel or copper in the spinel LiNi\(_x\)Cu\(_y\)Mn\(_{2-x-y}\)O\(_4\) as nickel or copper approach 0.5, which supports the findings of other research groups.\(^{12,33}\) It is also consistent with previous reports\(^{34,35}\) that oxygen deficiency is usually found in LiCu\(_{0.5}\)Mn\(_{1.5}\)O\(_4\). The results show that the impurity phase can be eliminated by slightly changing the Ni–Mn stoichiometry (LiNi\(_{0.45}\)Mn\(_{1.55}\)O\(_4\), Figure 4a) or by doping Cu into the NiMn spinel (Figure 4c–e).

According to Ohzuku et al., the integrated intensity ratios of the (400)/(311) peaks in spinel structure represent the extent of occupancy of the substituent ions on the tetrahedral site (8a).\(^{36,37}\) From Table 1, the integrated intensity ratio of (400)/(311) peaks generally decreases with the increase of Cu content. Exceptions are found in LiNi\(_{0.5}\)Mn\(_{1.5}\)O\(_4\) and LiCu\(_{0.5}\)Mn\(_{1.5}\)O\(_4\) where the oxide impurities are involved and may affect the related

---

**Figure 3.** Calculated DOS of Cu in Li\(_{1/2}\)Cu\(_{1/2}\)Mn\(_{3/2}\)O\(_4\) ((a) \(x = 1\), (b) \(x = 1/2\), (c) \(x = 0\)).

---

**Figure 4.** X-ray diffraction patterns of LiNi\(_x\)Cu\(_y\)Mn\(_{2-x-y}\)O\(_4\).
peak intensities. The decrease of the integrated intensity ratio of (400)/(311) peaks indicates that the occupancy of the substituent Cu in the tetrahedral sites (8a) increases when the Cu amount increases.

For LiNi$_{0.5-y}$Cu$_y$Mn$_{1.5}$O$_4$ samples, refinements are performed and Rietveld fitting results of LiNi$_x$Cu$_y$Mn$_{2-x-y}$O$_4$ are shown in Table 2, and the trend of lattice parameters change with respect to $y$ is depicted in Figure 5. From the plot, the lattice parameter decreases from $y=0$ to $y=0.05$, and then increases with the increase of $y$. The trend generally agrees with the results reported in previous literature. The site refinements also suggest that some Cu ions occupy the 8a tetrahedral sites instead of the 16d octahedral sites.

**Scanning Electron Microscopy (SEM).** SEM was performed to examine the particle size and morphologies of LiNi$_{0.5-y}$Cu$_y$Mn$_{2-x-y}$O$_4$ after 800 °C calcination. Figure 6a–f shows that in samples with no Cu or small amounts of Cu doping, spherical particles with 100 nm diameter were formed. It is also noted that when the amount of doped Cu increases (Figure 6d–f), the particle size increases and the shape of the particles becomes more faceted. For the LiCu$_{0.5}$Mn$_{1.5}$O$_4$ sample, the particle size is in the range of 300–500 nm, while the particle size for NiMn spinel sample is in the range of 50–100 nm.

Electrochemical Properties of LiNi<sub>x</sub>Cu<sub>y</sub>Mn<sub>2−x−y</sub>O<sub>4</sub>. The electrochemical properties of LiNi<sub>x</sub>Cu<sub>y</sub>Mn<sub>2−x−y</sub>O<sub>4</sub> (0 < x < 0.5, 0 < y < 0.5) were investigated in lithium half-cells. The charge/discharge profiles between 3.0 and 5.0 V are shown in Figure 7a and b. The cells were tested with a constant current of 0.1 mA/cm<sup>2</sup> applied to the cells. The LiNi<sub>0.45</sub>Mn<sub>1.55</sub>O<sub>4</sub> example exhibits the highest reversible capacity of 139.8 mAh/g, which is about 10 mAh/g higher than that of LiNi<sub>0.5</sub>Mn<sub>1.5</sub>O<sub>4</sub>. The small capacity reduction in LiNi<sub>0.5</sub>Mn<sub>1.5</sub>O<sub>4</sub> sample is attributed to the presence of NiO impurity. These two cells both have two distinct voltage plateaus around 4.7 V, which corresponds to the Ni<sup>3+</sup>/<Ni<sup>4+</sup> redox potential. A relatively small plateau can be found in the region around 4.0 V. This is attributed to the Mn<sup>3+</sup>/<Mn<sup>4+</sup> redox couple. Previous work has shown that calcination temperature may cause oxygen loss and can lower the average oxidation state of Mn and introduce Mn<sup>3+</sup> ions. For the LiNi<sub>0.45</sub>Mn<sub>1.55</sub>O<sub>4</sub> sample, the average oxidation state of manganese decreases further due to the decrease of Ni/Mn ratio; therefore, the capacity of the LiNi<sub>0.45</sub>Mn<sub>1.55</sub>O<sub>4</sub> sample at the 4.0 V region is larger than that of the LiNi<sub>0.5</sub>Mn<sub>1.5</sub>O<sub>4</sub> sample. When Cu ions are doped, the voltage plateau shifts from 4.7 to 4.95 V, and a new plateau appears between 4.2 and 4.6 V. When the doped Cu amount increases, the total capacity decreases, while the capacity between 4.0 and 4.6 V increases. Capacities contributed by the plateau around 4.0 V and by the plateau between 4.2 and 4.6 V in different materials are listed, respectively, in Table 3.

Rate Capability Testing. To study the rate capability of LiNi<sub>x</sub>Cu<sub>y</sub>Mn<sub>2−x−y</sub>O<sub>4</sub> (0 < x < 0.5, 0 < y < 0.5), electrodes were made with similar loading of active materials in each cell (about 20 mg of active material/cm<sup>2</sup>). For each material, the cells were charged to 5.0 V at constant low current rate (C/20) and discharged to 3.0 V at various current rates (C/20, C/10, C/5, and C/2). The measured discharge capacities are shown in Figure 8. For LiCu<sub>0.05</sub>Ni0.45Mn1.5O4 and LiCu<sub>0.1</sub>Ni0.40Mn1.5O4, the discharge capacities are highly retained when tested at a high discharge rate, while for Cu-free NiMn spinel samples the discharge capacity drops significantly at a high discharge rate. Note that the rate capability tests of LiCu<sub>0.05</sub>Ni0.45Mn1.5O4 and LiCu<sub>0.1</sub>Ni0.40Mn1.5O4 were also performed using a set of electrodes with much lower loading of active materials (about 10 mg active material/cm<sup>2</sup>) in each cell. The results are shown in Supporting Information Figure S7. A similar trend is seen in that LiCu<sub>0.05</sub>Ni0.45Mn1.5O4 has better rate capability than do the Cu-free NiMn spinel materials.

X-ray Absorption Near Edge Structure (XANES). X-ray absorption near edge structure (XANES) measurement was performed on the LiCu<sub>0.25</sub>Ni0.25Mn1.5O4 cathode material to study the active redox couple(s) in different voltage range.
Figure 9 shows the charge curve for a LiCu_{0.25}Ni_{0.25}Mn_{1.5}O_4 half cell that is used for in situ XAS experiment. The Cu, Ni, and Mn K-edge XANES spectra of LiCu_{0.25}Ni_{0.25}Mn_{1.5}O_4 measured as a function of voltage are shown in Figures 10 and 11. In each figure, (a) is the original spectra, and its second-order derivative is shown in (b) to investigate the distinct energy shifts. The spectra of related oxides are also provided as references for comparison. The pre-peak region of K-edge absorption peak of pristine sample is in the same position as the pre-edge peak for the CuO reference. This indicates that the oxidation states of Cu in the two materials are the same; thus Cu is $^{+2}$ in the pristine LiCu_{0.25}Ni_{0.25}Mn_{1.5}O_4. During the charging process, the position of Cu K-edge absorption peak remains unchanged until the voltage reaches 4.2 V. After that, the peak begins to shift to the higher energy side. The shift stops at around 4.7 V, and no significant energy shift can be observed at high voltage region between 4.7 and 5.0 V. The Cu spectra show that the Cu valence only changes between 4.2 and 4.7 V. Similar methodology was applied on Ni and Mn spectra. Ni is Ni$^{+2}$ in the pristine sample, and it starts to be oxidized from 4.7 V, and the K-edge energy shift continues until 4.9 V is reached. The Mn valence is $^{+4}$ in the pristine sample, and it remains unchanged during the entire charging process.

**Ex Situ XRD Measurements.** Ex situ XRD patterns for LiNi_{0.25}Cu_{0.25}Mn_{1.5}O_4 at different states of charge were measured between 4.2 and 5.0 V, to investigate the possible phase transition during Li deintercalation. Figure 13 shows the XRD
patterns of the LiNi\textsubscript{0.25}Cu\textsubscript{0.25}Mn\textsubscript{1.5}O\textsubscript{4} sample at different charged voltages during the second charging process. At low voltages between 4.2 and 4.6 V, the diffraction peaks shift to higher angles with increasing voltage, indicating that the lattice parameters are decreasing. However, at high voltages, no shifts in the diffraction peaks were observed, indicating the lattice parameters remain mostly constant. Although the amount and direction of shift may change with state-of-charge, no additional peaks appear during the entire charging process, suggesting the reaction remains single phase throughout the charging.

**Potentiostatic Intermittent Titration Technique (PITT).**

The potentiostatic intermittent titration technique was performed to identify the lithium diffusion coefficient associated with the high voltage plateau observed in the second charging cycle of the electrochemical curve. The diffusion coefficient can be extracted from the current response assuming a standard Cottrell solution for the lithium flux at the surface.\(^3\)\(^8\) Figure 14a shows the PITT profile for LiNi\textsubscript{0.25}Cu\textsubscript{0.25}Mn\textsubscript{1.5}O\textsubscript{4} between 4.5 and 4.9 V. Within this region, the current decays quickly at first, then takes 7 h to reach the limit value. The trends are consistent when different sets of samples are tested. Figure 14b shows the variation of chemical diffusion coefficients of Li ions in LiNi\textsubscript{0.45}Mn\textsubscript{1.55}O\textsubscript{4}, LiNi\textsubscript{0.5}Mn\textsubscript{1.5}O\textsubscript{4}, and LiCu\textsubscript{0.25}Ni\textsubscript{0.25}Mn\textsubscript{1.5}O\textsubscript{4}. The lithium diffusion coefficient is determined from the following equation where \(I\) is the current and \(L\) is the particle size. \(L\) is estimated from SEM images (Figure 6).

\[
D_{\text{Li}} = -\frac{d \ln(I)}{dt} = \frac{4L^2}{\pi^2} \cdot \frac{d}{dt} \frac{I}{L^2}
\]

The diffusion coefficient of lithium, \(D_{\text{Li}}\), can be calculated from the slope of the linear region in the plot of \(\ln(I(t))\) versus \(t\). \(D_{\text{Li}}\) changes with the lithium content. This trend shown in Figure 14b is similar to previous literature, but the values of the diffusion coefficient from our results are \(1-2\) orders of magnitude smaller than those obtained by Xia et al.\(^3\)\(^9\) The main source of discrepancy may come from the errors in estimation of the diffusion length for powered composite electrode as oppose to thin film electrode. The minimum of \(D_{\text{Li}}\) appears between 4.7 and 4.8 V. These coincide with the oxidation of Ni\textsuperscript{2+} to Ni\textsuperscript{4+}. Among the three samples, \(D_{\text{Li}}\) of LiCu\textsubscript{0.25}Ni\textsubscript{0.25}Mn\textsubscript{1.5}O\textsubscript{4} is 1 order of magnitude higher than that of LiNi\textsubscript{0.45}Mn\textsubscript{1.55}O\textsubscript{4} and LiNi\textsubscript{0.5}Mn\textsubscript{1.5}O\textsubscript{4}.

**General Discussion on LiNi\textsubscript{x}Cu\textsubscript{y}Mn\textsubscript{2-x-y}O\textsubscript{4}.**

1. **The Crystal Structure of LiNi\textsubscript{x}Cu\textsubscript{y}Mn\textsubscript{2-x-y}O\textsubscript{4}**

Although the results from first principles calculations performed at 0 K suggest that tetrahedral Cu is energetically less favored, results from XRD indicate that Cu ions do occupy tetrahedral sites in materials synthesized at high temperature. According to Shannon et al., the effective ionic radius of Cu\textsuperscript{2+} (0.57 Å) is slightly smaller than that of Li\textsuperscript{+} (0.59 Å) if the atoms are tetrahedrally coordinated.\(^4\) When a small amount of Cu ions are doped into the NiMn spinel materials, most of the Cu\textsuperscript{2+} ions may occupy the tetrahedral sites, leading to a smaller lattice parameter than undoped materials. However, when more Cu ions are doped, Cu\textsuperscript{2+} will also occupy the octahedral sites that were originally occupied by Ni\textsuperscript{2+} ions. Because the effective ionic radius of octahedral Cu\textsuperscript{2+} (0.73 Å) is larger than that of octahedral Ni\textsuperscript{2+} (0.69 Å),\(^3\) the decrease of lattice parameter is gradually compensated, and the lattice parameters will finally increase with the increase of doped Cu amount.

2. **The Voltage Profile and Capacities of LiNi\textsubscript{x}Cu\textsubscript{y}Mn\textsubscript{2-x-y}O\textsubscript{4}**

Although in previous research,\(^1\)\(^3\) the high voltage plateau of 4.95 V was attributed to the oxidization of Cu\textsuperscript{2+} to Cu\textsuperscript{3+}, our results show that this may not be true. The calculated voltage corresponding to the oxidization from Cu\textsuperscript{2+} to Cu\textsuperscript{3+} in

Figure 12. (a) The Mn K-XANES spectra of LiCu\textsubscript{0.25}Ni\textsubscript{0.25}Mn\textsubscript{1.5}O\textsubscript{4} measured as a function of voltage. (b) Second-order derivative of Mn K-edge XANES spectra of LiCu\textsubscript{0.25}Ni\textsubscript{0.25}Mn\textsubscript{1.5}O\textsubscript{4} measured as a function of voltage.

Figure 13. The XRD pattern of the LiNi\textsubscript{0.25}Cu\textsubscript{0.25}Mn\textsubscript{1.5}O\textsubscript{4} sample at different voltages during the second charge process.
nondefect spinel LiCu_{0.25}Mn_{1.5}O_{4} is only 4.44 V, much lower than the experimentally measured high voltage plateau at around 4.95 V, but quite close to the low voltage step at around 4.2 V. Cu^{3+} ions cannot be further oxidized to higher valences, and this conclusion is also supported by our XANES results obtained from the materials. The discharge capacity of LiNi_{0.25}Cu_{0.25}Mn_{1.5}O_{4} at C/20 is around 95 mAh/g, and 97% of them can be retained at C/2. On the other hand, the discharge capacity of LiNi_{0.5}Mn_{1.5}O_{4} at C/20 is 122 mAh/g, but it drops to 76 mAh/g at C/2. The improvement of rate performance of LiNi_{0.25}Cu_{0.25}Mn_{1.5}O_{4} may come from two major sources. (1) The ionic conductivity of the materials is improved by the enhancement of Li mobility. As shown in Figure 14b, the measured lithium diffusion coefficient of LiCu_{0.25}Ni_{0.25}Mn_{1.5}O_{4} is significantly larger than that of LiNi_{0.5}Mn_{1.5}O_{4} or LiNi_{0.25}Mn_{1.5}O_{4}. A possible reason is that the cation distribution of LiNi_{0.25}Cu_{0.25}Mn_{1.5}O_{4} varies with the change of cation composition. When the amount of Cu doping is in a certain range, the corresponding cation arrangements can provide more local environments that are similar to Figure 1b, and therefore may significantly reduce the Li diffusion barriers and improve the overall Li mobility. (2) The LiCu_{0.25}Ni_{0.25}Mn_{1.5}O_{4} system experiences smaller strains during the Li-extraction than the nondoped NiMn spinel. For LiNi_{0.5}Mn_{1.5}O_{4} and LiMn_{2}O_{4}, a second or third cubic phase will form during the charging stage.\textsuperscript{41} As the coexistence of two phases usually causes lattice mismatch, high stress and strain may be introduced into the nondoped NiMn spinel and affect the stabilities of the systems, especially at high rate. For LiCu_{0.25}Ni_{0.25}Mn_{1.5}O_{4}, however, the ex situ XRD results (Figure 13) show that only single cubic phase is present during the charging stage. No phase transition occurs inside the materials, as the experienced strains are much less and the system is therefore more stable at high rate. Besides the above two sources, the effect of electrical conductivity may also play a role. It was already reported by Kunduraci et al.\textsuperscript{10} that cation ordered P4_32 spinel exhibits less capacity retention than does the disordered spinel at fast discharge rates. This phenomenon is attributed to the higher electronic conductivity of the disordered spinel. Molenda et al.\textsuperscript{15} also showed that the electrical conductivity of LiCu_{x}Mn_{2-x}O_{4} would increase with the Cu amount. There are factors that may negatively affect the rate capability of the materials as well, such as the increased particle sizes for Cu-doped NiMn spinel and the presence of unmovable tetrahedral Cu that may block the Li diffusion channels. From the experimental results obtained in this work, however, these factors can be compensated by the positive effects discussed previously.

### Conclusion

In this work, a series of bidoped spinel oxides of LiNi_{x-Cu}Cu_{2-x}Mn_{2-x-y}O_{4} (0 < x < 0.5, 0 < y < 0.5) have been studied.

---

**Figure 14.** (a) PITT profile for LiNi_{0.25}Cu_{0.25}Mn_{1.5}O_{4} sample. (b) Diffusion coefficient of LiNi_{0.45}Mn_{1.55}O_{4}, LiNi_{0.5}Mn_{1.5}O_{4} and LiNi_{0.25}Cu_{0.25}Mn_{1.5}O_{4}.
Their crystal structure, electronic structure, and electrochemical properties are compared. A new explanation of the voltage profile for LiNi$_2$CuMn$_{2-x}$O$_4$ is proposed, supported by the results from first principles computation, and confirmed by electrochemical property measurement and in situ XAS experiment. We have shown that Ni, Cu, and Mn are 2+, 3+, and 4+, respectively, in the pristine sample. Cu cannot be further oxidized to Cu$^{4+}$, and the plateau at 4.95 V originates from extra electrons possibly provided by oxygen ions. Li diffusion activation barriers of LiM$_{1-x}$Mn$_{2+y}$O$_4$ ($M = Ti, V, Cr, Fe, Co, Ni, and Cu$)$ are calculated. The results show that different dopants can have significant effects on the Li diffusion barriers. Although the capacity of the doped spinel materials decreases with the increasing doped Cu amount, LiCu$_{0.25}$Ni$_{0.25}$Mn$_{1.5}$O$_4$ spinel oxide exhibits higher capacity than does undoped LiNi$_{0.5}$Mn$_{1.5}$O$_4$ spinel at high rates. The good rate capability of LiCu$_{0.25}$Ni$_{0.25}$Mn$_{1.5}$O$_4$ spinel oxide is attributed to the single phase reaction during charging, the lower Li diffusion barrier induced by Cu doping, and possibly higher electronic conductivity contributed by Cu doping.
